ABSTRACT

Is there a link between loose monetary conditions, credit growth, house price booms, and financial instability? This paper analyzes the role of interest rates and credit in driving house price booms and busts with data spanning 140 years of modern economic history in the advanced economies. We exploit the implications of the macroeconomic policy trilemma to identify exogenous variation in monetary conditions: countries with fixed exchange regimes often see fluctuations in short-term interest rates unrelated to home economic conditions. We use novel instrumental variable local projection methods to demonstrate that loose monetary conditions lead to booms in real estate lending and house prices’ bubbles; these, in turn, materially heighten the risk of financial crises. Both effects have become stronger in the postwar era.

1. Introduction

How do monetary and credit conditions affect housing booms and busts? Do low interest rates cause households to lever up on mortgages and bid up house prices, thus increasing the risk of financial crisis? And what, if anything, should central banks do about it? Can policy directed at housing and credit conditions, with monetary or macroprudential tools, lead a central bank astray and dangerously deflect it from single- or dual-mandate goals? Such questions suffice the debate on the causes of and responses to the global financial crisis.

Yet while the crisis has passed, finding the answers to these questions still looms large in the policy challenges facing policymakers and, especially, central banks. In an effort to defroth the housing

Notes: For mortgage lending, the financial institutions covered include commercial banks (CB) and other financial institutions (OFI) such as savings banks, credit unions, and building societies. Data generally cover all monetary financial institutions. The following exceptions apply. Australia: pre-WW2 mortgage loans are from savings banks only; Belgium: pre-WW2 mortgage loans are OFIs only; Canada: mortgage loans before 1954 are OFIs only; Germany: pre-1920 mortgage loans are OFIs only; Denmark: pre-WW2 mortgage loans are OFIs only; Japan: pre-WW2 mortgage loans are CBs only; Norway: pre-1900 mortgage loans are mortgage banks only; USA: pre-1896 real estate loans are savings banks only.

Sources: Jordà et al. (2014) and Knoll et al. (2014).

In this current environment, to say that the recent crisis and its aftermath have led to a reassessment of the importance of housing finance for the macroeconomy would be a distinct understatement. Dissecting the sources of house price fluctuations and their effect on household spending, residential investment, the health of financial intermediaries, and ultimately on real economic outcomes, has become a top research priority. In addition to Mian and Sufi’s (2014) influential book, a rapidly growing literature investigates the nexus between monetary policy and house prices as well as the implications of house price fluctuations for monetary policy (Adam and Woodford, 2013; Allen and Rogoff, 2011; Del Negro and Otrok, 2007; Glaeser et al., 2010; Goodhart and Hofmann, 2008; Jarocinski and Smets, 2008; Kuttner, 2012; Williams, 2011). The link between monetary conditions, mortgage borrowing, and house price appreciation has attracted considerable attention in some quarters (e.g., Bernanke, 2010; Leamer, 2007; Taylor, 2007). Many have wondered whether the low interest rate environment that prevailed in the years before the 2008 crisis contributed to the house price booms experienced in many Western economies before the recent crash.

House price data are easily available from institutions such as the OECD or the Federal Reserve Bank of Dallas for about 20 advanced economies starting in the mid-1970s, but are much more scattered for earlier times. The same can be said of mortgage credit data. As a result, previous research has, with few exceptions such as Bordo and Landon-Lane (2013) or Reinhart and Reinhart (2011), focused on the decades of the so-called Great Moderation. But such a limited sample, focused on a historically atypical era of peculiar macroeconomic and financial tranquility, calls into question the robustness of the research and the conclusions currently being used as a guide to policy. Housing booms and busts, just like financial crises, are rare events. In order to gain statistical power one needs much longer samples, but these data are very difficult to obtain. Our work fills this void.

This paper analyzes the link between monetary conditions, credit growth, and house prices using data spanning 140 years of modern economic history across 14 advanced economies. Such a long and broad historical analysis has become possible by compiling two datasets, both the result of an extensive multi-year data collection effort. The first dataset covers disaggregated bank credit data, including real estate lending to households and non-financial businesses for 17 countries (Jordà et al., 2014). The second dataset, compiled for a study by Knoll et al. (2014), presents newly unearthed data covering long-run house prices for 14 out of the 17 economies in the first dataset, from 1870 to 2012. This is the first time both datasets have been combined.

![Fig. 1. Bank mortgage and non-mortgage lending to GDP, 1870–2011, average for 17 countries.](image-url)
We make three core contributions. First, we discuss long-run trends in mortgage lending, home ownership, and house prices and show that the 20th century has indeed been an era of increasing “bets on the house.” The strong rise in aggregate private debt over GDP that can be observed in many Western economies in the second half of the 20th century has been mainly driven by a sharp increase in mortgage debt. Mortgage credit has risen dramatically as a share of banks’ balance sheets from about one third at the beginning of the 20th century to about two thirds today. As a result, the intermediation of savings into the mortgage market has become the primary business of banking, eclipsing the stylized textbook view of banks financing the capital formation of businesses.

Second, turning to the cyclical fluctuations of lending and house prices we use novel instrumental variable (IV) local projection methods to show that throughout history loose monetary conditions were closely associated with an upsurge in real estate lending and house prices. House prices, interest rates, and credit aggregates may be jointly determined in equilibrium, and this makes establishing causality difficult. Pairing local projections with IV methods allow us to tease out this causal effect, where we exploit the implications of the well-known policy trilemma in international macroeconomics (Obstfeld and Taylor, 2004). Broadly speaking, when countries peg to some base currency they effectively import the base economy’s monetary policy, even if it is at odds with home economic conditions. Exchange rate pegs therefore provide a source of exogenous variation in monetary conditions. By conditioning on a rich set of domestic macroeconomic controls, we are able to isolate exogenous fluctuations in the short-term interest rate imported via the peg and trace the effect of these fluctuations over time on other variables.

Third, we also expose a close link between mortgage credit and house price booms on the one hand, and financial crises on the other. Over the past 140 years of modern macroeconomic history, mortgage booms and house price bubbles have been closely associated with a higher likelihood of a financial crisis. This association is more noticeable in the post-WW2 era, which was marked by the democratization of leverage through housing finance. These findings have important implications for the debate about central bank policy in the aftermath of the crisis: how should policymakers think about the financial stability risks that stem from extended periods of ultra-low interest rates? How should they be weighed against the objective of restoring full employment? The long-run historical evidence uncovered in this study clearly suggests that central banks have reasons to worry about the side-effects of loose monetary conditions. During the 20th century, real estate lending became the dominant business model of banks. As a result, the effects that low interest rates...
Fig. 3. Trends in home ownership rates for six countries.

Fig. 4. Real home prices, relative to CPI, in the 20th century.
have on mortgage borrowing, house prices and ultimately financial instability risks have become considerably stronger.

While these historical insights suggest that the potentially destabilizing byproducts of easy money must be taken seriously, it is by no means an obvious conclusion that tighter monetary conditions are always the right answer. From a policy perspective, the most relevant implication of our study is that central banks must be mindful of these side-effects and address them, possibly through the greater use of macro-prudential tools. Macroeconomic stabilization policy has implications for financial stability, and vice versa. The idea that these two objectives can or should be looked at in isolation is not borne out by modern macroeconomic history.

2. Old questions, new data

As discussed in the introduction, this study combines two newly assembled historical datasets. The first dataset covers long-run disaggregated bank credit data for 17 advanced economies since 1870. It tracks the share of mortgage lending in total bank lending for most countries back to the 19th century (Jordà et al., 2014). Moreover, for a cross-section of countries, it makes possible to back out the share of bank credit to businesses and to households. The underlying data come from a broad range of sources, including economic and financial history studies, journal articles, yearbooks of statistical offices and central banks, as well as sources from central and private bank archives. For some countries, the dataset incorporates existing series from economic historians or statistical offices.

We combine these historical credit data with a novel dataset covering long-run house prices for 14 advanced economies from the 19th century until today (Knoll et al., 2014). This newly assembled source represents the first major attempt to construct long-run house price indices for the advanced economies. Relative to previous studies of long-run trends in house prices, such as Bordo and Landon-Lane (2013), it approximately doubles the number of country-year observations. The dataset reaches back to the 1870s in the case of Australia, Belgium, Denmark, France, the Netherlands, Norway, and Sweden. Data for the U.S. and the U.K. start in the 1890s and from the early 1900s in the case of Finland, Germany, Switzerland, and Japan. Data for Canada start in the early 1920s. Compared to previous studies, house price series for the U.K., Japan, and Switzerland are extended by more than 30 years and for more than 40 years in the case of Belgium. Relying on more than 60 different sources, the data combine existing indices with new series constructed on the basis of published and unpublished materials.

Table 1 summarizes the coverage of the credit and house price data as well as the principal type of the house price index used. Some caveats are worth discussing. The construction of historical house price indices entails a number of specific challenges. The house is a bundle of the
structure and the land used in its construction. An ideal index would capture the appreciation of the price of a standard, unchanging house which is hard to identify. This makes the construction of house price indices complex and various methods have been proposed. As a result, the reconstruction of historical house price data requires a number of concessions between the ideal and the possible. The historical data vary across countries and time, with respect to the method used for index construction, and the within-country geographic coverage and the type of dwellings. Some series are calculated on the basis of list or transaction prices while others rely on appraisal values. All of these issues may pose a challenge to comparability. However, at present, these data represent the best possible and most comprehensive basis for an analysis of house prices in the long run.

Over the last 140 years, the business of banking has gradually evolved from business loans to mortgages. Fig. 1 displays the path of mortgage and non-mortgage lending (mostly unsecured lending to

Fig. 7. The trilemma-based IV: changes in short-term interest rates in home and base countries.

businesses) relative to GDP from 1870 to the present for the sample of 17 economies for which we have data (a slightly larger sample than is available for house prices). It is immediately evident from the graph that mortgage borrowing has accelerated markedly in almost all advanced economies after WW2. At the beginning of the 20th century, mortgage credit stood at about 20% of GDP on average. By 2010, average mortgage credit approached 70% of GDP. Banks and households in the Western world have been betting the house. This is true even in countries such as Switzerland and Germany where there has been much less political emphasis and subsidization of home ownership.

Fig. 2 presents the data disaggregated by country. The figure shows that for most countries, mortgage lending now accounts for the larger part of bank lending. A substantial share of the increase in private sector debt levels in the past decades—a process often referred to as financialization—has been driven by the increase of real estate credit. Unsecured lending to the business sector has remained largely stable. Non-mortgage bank lending has hovered in the 40%-50% range as a ratio to GDP on average.

As a result of these trends, mortgage credit now accounts for nearly three fifths of the typical balance sheets of banks in advanced economies while only two fifths go to businesses and consumers for purposes other than the purchase of real estate. From an economic point of view, this is noteworthy for at least two reasons. First, textbook models of the banking sector assume that the role of the banking sector is to intermediate household savings into business investment. This was a useful description of the activities of the financial sector in the first half of the 20th century, but it is no longer true today. The banking sector chiefly intermediates savings between households for the purpose of real estate acquisition. Second, the key economic function of banks no longer seems to correspond to their business model. The advantage of banks relative to direct financial intermediation is to reduce information asymmetries through screening and monitoring of borrowers. However, this function is arguably much more important for business financing than for standardized mortgage contracts.

The rise in mortgage credit over the second half of the 20th century has financed a substantial expansion of home ownership in Western economies. Karl Marx noted in Das Kapital that according to the census of 1861 there were 20 million people living in England and Wales whereas the number of home owners was given as 36,000. Back then, far fewer than 1% were among the fortunate who owned property. In our times, the debate about the top 1% is back, but it is clear that home ownership is distributed much more widely today with home ownership rates north of 60% (see, e.g., Bonnet et al. (2014)).

By the 1920s home ownership rates in England had already increased to about 20% from the days of Marx’s writing. In the U.S. and thanks to the 1944 G.I. Bill, home ownership rates would cross the 50% mark shortly after WW2. Explicit government policies and generous subsidies to boost home ownership were, by and large, a widespread phenomenon of the postwar decades. Today the view that home ownership is a key constituent of national identity is widely shared and supported by growing government intervention. Fig. 3 illustrates this pervasive increase in home ownership.

The growth of mortgage credit has not only led to an expansion of home ownership, it has left its mark on house price dynamics. The data collected and analyzed by Knoll et al. (2014) show that the path of global house prices in the 20th century has not been continuous. Real house prices, deflated with the consumer price index (CPI), remained stable from 1870 until the middle of the 20th century after which they gradually grew, as Fig. 4 shows. Relative to income, house prices initially fell in many countries before stabilizing or increasing over the past few decades. This is displayed in Fig. 5. Over the last 140 years, house prices have risen significantly relative to the price of consumption goods, but have lagged real income growth.

Fig. 5 also shows that there are large swings in house price to income ratios. Periods of pronounced increases are often followed by abrupt corrections. Later in the paper we study if such swings can be explained by changes in credit conditions. In addition, Fig. 5 shows that there is considerable heterogeneity in house price trends across economies that otherwise have similar characteristics and comparable long-run growth performance. The international experience can be broadly synthesized into three categories. House prices in Australia have increased more than income since 1870. In contrast, house prices have lagged...
income growth by a wide margin in countries such as Belgium, Sweden, Germany, and the U.S. Finally, for a third group of countries consisting of Canada, the U.K., Japan and possibly France, house prices have mostly grown on a par with income.

4. A Eurozone parable

What role have monetary conditions played in mortgage credit expansions and house price booms? Later sections proceed at some length with a formal econometric investigation. Here we motivate the analysis using a recent dramatic example based on the divergent macroeconomic and financial outcomes of the core and periphery of the Eurozone.¹

Upon the creation of the Eurozone in 1999, member states signed up to a common monetary policy administered by the ECB. The loss of monetary policy autonomy was an extreme version of the trilemma: with capital mobility enforced by treaty within the EU, and with exchange rates irrevocably fixed by the no-exit feature of the euro, each member state had no scope to set monetary conditions to suit the outlook for their macroeconomy. Such a choice might make economic sense under the tradeoffs embodied in the theory of optimum currency areas (Kenen, 1969; Mundell, 1961), but it would still be a tradeoff, and some cost would attach to the sacrifice of monetary autonomy. But how big a cost?

Absent perfectly synchronized business cycles and frictionless adjustments, common monetary policy administered by the ECB meant that for some countries monetary conditions would be “too loose,” whereas for some others they would be “too tight.” Booming economies would be encouraged to grow, slumping economies to decline, resulting in greater real economic instability.²

However, business-cycle models that include an explicit role for the financial sector suggest that other dangers lurk. If transmission works through the credit channel of monetary policy, then countries facing excessive monetary ease would see larger credit booms than normal. Moreover, these effects could be magnified via cross-border capital flows, and with the possibility that these credit booms could spill over into asset prices, altogether elevating the risk of financial instability. Prima facie, the events in the Eurozone in the 1999–2008 pre-crisis phase seem to conform to this narrative.

Fig. 6 shows some salient features of the Eurozone episode. The focus is on two crisis countries, Ireland and Spain, plus Germany. Before the crisis, Ireland and Spain had fast-growth economies, credit booms with large increases in mortgage lending, and rapid housing price increases (in real and nominal terms, and relative to income per person). After 2008 all of these trends went into sharp reverse, with a banking crisis in each country, deep depressions and high unemployment, and extremely high levels of fiscal distress. Quickly worsening fiscal positions arose, driven by lost output and by banking sector bailout and recapitalization costs. In contrast Germany grew more slowly in the 1995–2008 period, had no credit, mortgage, or housing booms, and had a more moderate recession in 2008 soon followed by recovery and a return to growth. Banking crisis effects were still present in Germany (some banks suffered losses on U.S. subprime and euro periphery exposures) but these problems were shrugged off and bailout costs easily absorbed by a fiscal position that started strong and did not deteriorate very much.

Fig. 6, panel (a) shows the interest rate environment of the three countries and it accords with the standard narrative view of the key mechanisms. Based on a study by Malkin and Nechio (2012), we show the “optimal” Taylor-rule implied policy interest rates for the three countries against the actual ECB policy rate for the 1999–2007 period. Given the rapid output growth and above target inflation in Ireland and Spain, the Taylor rule policy rate for these economies would have been much tighter, perhaps 500 basis points (bps) tighter and sometimes more. In contrast, relatively slow growth and low inflation in Germany meant that its Taylor rule policy rate would have been slightly lower than that chosen by the ECB, maybe by as much as 100 bps on average. Viewed as a natural experiment, the question is whether these differences in monetary policy treatment led to different outcomes in Ireland and Spain using Germany as control.

Panel (b) in Fig. 6 shows that outcomes in the credit markets differed by treatment. In Ireland and Spain a large expansion in private debt was driven in large part by the growth of real estate backed mortgages. The level of mortgage debt to GDP in each country doubled in the space of about 8 years. Meanwhile, the level of mortgage debt to GDP was stable in Germany over the entire period at about 50% of GDP.

Panel (c) in Fig. 6 shows the very different outcomes in house price trends. The house price to income ratio was nearly stable in Germany over the entire period, declining slightly by 20% over the decade. In contrast, house price to income ratios in Ireland and Spain rose by 65%–75% over the same time frame.

These data provide some support to the hypotheses, often asserted in analyses of the Eurozone crisis, that periphery countries experienced an exogenous monetary easing which went on to fuel credit and housing price boom and bust cycles—ending in economic crises and output disasters for countries like Ireland and Spain. Yet can we establish a causal link between monetary conditions on the one hand, and mortgage and house price boom-bust cycles, as well as financial instability, on the other hand? More to the point, can we get formal statistical

¹ For background see, e.g., Allen et al. (2011), Lane (2012), and O’Rourke and Taylor (2013).
² The Mundellian output volatility effects of fixed-versus-floating exchange rate regime choice are well known. On the empirical evidence see di Giovanni and Shambaugh (2008).
evidence from a large body of empirical macroeconomic evidence that looks systematically at many episodes over time and space rather than a case study based on a sample of three countries? The remainder of this paper will try to answer both of these questions in the affirmative.

5. Exogenous perturbations to monetary conditions: the trilemma as a natural experiment

Using short-term interest rates as a proxy for monetary conditions, what is the causal link to mortgages and house prices based on our large sample of macro-financial data covering the history of advanced economies since 1870? The key empirical hurdle in answering this question is that home interest rates may be endogenously determined. Averting simultaneity bias requires identifying movements of the home interest rate that are not the result of the reaction by local policymakers to domestic economic conditions, including output, inflation, and the evolution of credit and housing prices.

The macroeconomic policy trilemma offers a possible solution to the identification conundrum. This foundational proposition of international macroeconomics states that a country cannot simultaneously pursue the three mutually incompatible policy goals of fixed exchange rates, capital mobility, and monetary policy autonomy (Obstfeld and Taylor, 2004). It must give up one of the three goals, or equivalently choose to pursue only two out of the three. A simple corollary of interest parity, the trilemma has been central to open economy macroeconomics since the work of Mundell and Fleming, and in the last decade has seen extensive empirical testing and validation (Aizenman et al., 2008; Klein and Shambaugh, 2013; Obstfeld et al., 2004, 2005).

Suppose the home country $i$ at time $t$ has either a fixed (pegged) or flexible (floating) exchange rate with respect to some other base country. This is denoted by the variable $PEG_i = 1$ and $PEG_i = 0$, respectively. Suppose the home country $i$ at time $t$ is either open or closed to international capital markets. This is denoted by the variable $KOPEN_i = 1$ and $KOPEN_i = 0$, respectively.

Let $r_{it}$ denote the short-term nominal interest rate in the home country, and let $r^*_{it}$ denote the short-term nominal interest rate set by policymakers in country $i$'s base country. Note that the home country index $i$ is used since base countries differ by $i$. Furthermore, changes over the period are denoted $\Delta r_{it}$ and $\Delta r^*_{it}$, respectively. We denote with $X_{it}$ a set of domestic macroeconomic controls used in determining the home interest rate in the absence of a peg. A simple algebraic expression of the trilemma suitable for our empirical application sets out the observed change in the home interest rate as a function of the change in the base country interest rate and the configuration of the exchange rate regime and capital mobility:

$$\Delta r_{it} = a + b[PEGIN_i \times KOPEN_i \times \Delta r^*_{it}] + \Theta X_{it} + u_{it}. \quad (1)$$

To develop intuition, think about two polar cases. In the case of a floating regime or capital immobility, there need be no correlation at all between home and base rates, $PEG_i \times KOPEN_i = 0$ and then $r_{it}$ and $r^*_{it}$ would be completely delinked. In the case of a truly hard peg with capital mobility $PEG_i \times KOPEN_i = 1$ and with perfect correlation ($b = 1$) then changes in the observed home and base rates, $r_{it}$ and $r^*_{it}$ would be equalized. A possible risk premium would be captured by the intercept when $a \neq 0$, but the simple theory would entail a perfect pass-through with the coefficient $b = 1$ in the pegged case. Other influences on the home interest rate are captured by the controls $X_{it}$. The error term $u_{it}$ is assumed to be well behaved.

In practice, the dichotomy between fixed and flexible regimes is not as clean and intermediate regimes muddy the simple story described above. Likewise, capital mobility may not be properly captured in a binary variable, but rather by a continuous measure, as we assume below. The implications for the coefficient $b$ then depend on the nature of local monetary policy reaction within whatever room for maneuver the regime permits. In a target-zone model with a home central bank that can “lean against the wind” theoretical simulations by Obstfeld et al. (2005) show that the coefficient $b$ may be below one, but still above zero.

For our analysis, the trilemma Eq. (1) provides a method for identifying home interest rate perturbations that are unrelated to local economic conditions. Base countries, such as the U.S. in the Bretton Woods era, have monetary policy autonomy by definition. But, as conventionally understood, their authorities would pay no attention whatsoever to economic conditions in partner countries when making policy choices.

The examples are legion. Famously, the U.S. decision to raise rates in 1927–1928 in reaction to local asset market conditions imposed stress on the U.K. and other countries trying to cling to the interwar gold standard. Over a longer period so did the steady tide of gold reserves

Notes: $\Delta r$ denotes change from year $t - 1$ to $t + h$. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Country-based cluster-robust standard errors in parentheses. Coefficient estimates of fixed effects and controls not reported. The set of controls includes: (i) the change in short-term interest rate; (ii) the change in long-term interest rate; (iii) the change in mortgages to GDP ratio; (iv) the change in real house prices as a ratio to per capita income; (v) real per capita GDP growth; (vi) the change in the investment to GDP ratio; (vii) the change in the ratio of non-mortgage loans to GDP ratio; (viii) CPI inflation; and (ix) the current account to GDP ratio. We include contemporaneous terms and two lags. The full sample starts in 1870 and ends in 2010. Kleibergen and Paap (2006) statistic for weak instruments reported. World wars omitted. See text.
flooding into a Banque de France which was all too eager to sterilize them (Ahamed, 2009; Eichengreen, 1992; Irwin, 2010). At the G-10 Rome meetings in 1971, U.S. Treasury Secretary John Connally declared to the world that “the dollar is our currency, but it’s your problem.” In June 1972 President Richard Nixon expressed the same sentiment rather more colorfully, caught on the ever-running Watergate tapes, when he was asked by aide H. R. Haldeman about an incipient currency crisis in Italy and blurted out his famous response: “Well, I don’t give a shit about the lira.”

In the final days of Bretton Woods, it was the turn of the U.S. to fall under exchange rate pressure, but in the dead of the night the German government withdrew its support, allowing the dollar to fall against the mark, a decision that was later justified by Chancellor Schmidt with an appeal to the arcane legal doctrine ultra posse nemo obligatur. The same problem of cooperation under fixed exchange rates resurfaced in the 1992 ERM crisis when, at the September 5 meeting in Bath, the German Finance Minister Theo Waigel replied to the repeated pleas of his British counterpart, Norman Lamont, for the Bundesbank to loosen monetary policy: “My dear Lamont, you have asked that question four times...if you ask again, I will get our helicopter ready to take us back.”

Still today the recurrent mutterings about currency wars in recent years tell the same story: when considering not just the plight of unilateral dollarizers such as Panama, Ecuador, or El Salvador, but even the general spillovers from U.S. monetary policy to the quasi-“dollar bloc” of emerging economies, especially India and China, players on all sides harbor few illusions that the Fed will shape its interest rate policies to suit conditions in far away countries.

In sum, to peg is to sacrifice monetary policy autonomy, at least to some degree. Given this understanding of the key constraints in past and present international monetary regimes it is natural for us to treat the term $z_{it} = [\text{PEG}_{it} \times \text{KOPEN}_{it} \times \Delta r_{it}^*]$ on the right-hand side of Eq. (1) as an exogenous influence on local monetary conditions in the home economy, notwithstanding other effects captured by the rest of the terms in the equation. Thus $z_{it}$ will serve in what follows as the IV for changes in home interest rates, and will permit us to identify causal relationships from rates to mortgage credit and to house prices.

The formal definition of the IV $z_{it}$ consists of multiplying the change in relevant base country short-term interest rate $\Delta r_{it}^*$ by the product of $\text{PEG}_{it}$ and of $\text{KOPEN}_{it}$. The peg indicator equals 1 when the home country is pegged to the base country in both year $t$ and year $t - 1$. For the sample of countries we study, a description of the relevant base countries in each historical era is presented in Table 2. Prior to WW2, peg codings are taken from Obstfeld et al. (2004, 2005). After WW2 they are gleaned from Ilzetzki et al. (2008) and updates thereto. Prior to 1914 we treat the U.K. as the base for everyone, and after 1945 we treat the U.S. as the base for everyone, with the exception of EMS/ERM/Eurozone countries for which Germany is the base after 1973. In the interwar period, the choice of a suitable base country is more challenging and subjective given the instability of the interwar gold standard period; we follow Obstfeld et al. (2004) in using a hybrid “gold center” short-term interest rate, which is an average of U.S., U.K., and French short term rates depending on which of the three countries was pegged to gold in a particular year; our results are not sensitive to this choice and we replicate our findings using any one of these three countries as the sole interwar base as in Obstfeld et al. (2004). The capital mobility indicator is based on the index (from 0 to 100) in Quinn et al. (2011). We use a continuous version of their index rescaled to the unit interval, with 0 meaning fully closed and 1 fully open.

the panel is not balanced because data availability varies by country. However, Owyang et al. (2013) observed over roughly 140 years. This section discusses how we exploit this feature to identify the home economic conditions. This natural pseudo-experiment pro-

6. IV local projections

Across different periods in history, countries with fixed exchange regimes often saw fluctuations in short-term interest rates unrelated to home economic conditions. This natural pseudo-experiment provides an exogenous source of variation in home short-term interest rates. This section discusses how we exploit this feature to identify the dynamic multipliers of mortgages and house prices in response to these pseudo-natural experiments in the short rate.

The empirical strategy combines the local projection approach (Jordà, 2005) with IV methods. Recent papers that have used this particular combination of procedures include Leduc and Wilson (2013) and Owya et al. (2013). Recall that the data that we will analyze are a long panel of 14 countries observed over roughly 140 years. However, the panel is not balanced because data availability varies by country.

</table>

Notes: \( \Delta_y \) denotes change from year \( t-1 \) to \( t+h \). \( * p < 0.10, ** p < 0.05, *** p < 0.01 \). Country-based cluster-robust standard errors in parentheses. Coefficient estimates of fixed effects and controls not reported. The set of controls includes: (i) the change in short-term interest rate; (ii) the change in long-term interest rate; (iii) the change in mortgages to GDP ratio; (iv) the change in real house prices as a ratio to per capita income; (v) real per capita GDP growth; (vi) the change in the investment to GDP ratio; (vii) the change in the ratio of non-mortgage loans to GDP ratio; (viii) CPI inflation; and (ix) the current account to GDP ratio. We include contemporaneous terms and two lags. World wars omitted. IV estimates from Table 5 repeated here for convenience. See text.

Fig. 7 and Table 3 verify that if \( z_{it} \) has the potential to be a valid instrument, for all the reasons given above, then it is certainly not a weak instrument. The scatter plots in Fig. 7 are simple bivariate plots of the change in the home short rate \( \Delta y_i t \) against the putative instrument \( PEG_i t \times KOPEN_i t \times \Delta \sigma_i t \), for our panel dataset, looking separately at both the pre-WW2 and post-WW2 samples. That is, we estimated (1) and no controls \( X_{it} \), as in Panel (a) and Columns (2) and (3) of Table 3, then plotted the data and the line of best fit. The correlations are seen to be strong; the slope coefficients \( b \) in each case are significant at the 1% level. The F-statistics exceed 15 in all cases, and exceed 60 in the full sample. The coefficients \( b \) in each subsample, and in the full sample, are close to \( 1 / b \), rather than 1, so the pass-through from base to home rates is not one-for-one, but is significant; these results very closely match those in Obstfeld et al. (2004, 2005).

We now move on and then apply the IV \( z_{it} \) to the central estimation problem in our paper. In a setting like ours, the approach of using exchange rate regimes to identify exogenous shocks has great promise as a way of estimating policy impacts, and it builds on several applied works which embrace a similar logic: di Giovanni and Shambaugh (2008) use the same instrument to look at output volatility in fixed and floating exchange rate regimes; Iltz et al. (2013) partition countries by exchange rate regimes to study the impacts of a fiscal policy shock. In this paper we use this strategy to gain a clean identification of the workings of the credit channel and its implications for mortgage and house price booms and busts over the course of macroeconomic history.

We explain the details of our dataset in the appendix. Note also that we exclude the two world wars.

Let \( \Delta y_{it} - 1 = y_{it} - y_{it-1} \) denote the response variable of interest, for example, the change in house prices (measured as the log of the ratio of real house prices to income per capita) from the base year \( t-1 \) up to year \( t + h \) with \( h = 0, 1, \ldots, H \). The subindex \( i \) denotes the country. Let \( \Delta y_i t \) denote the change in the home short-term interest rate, although in general it refers to any variable whose perturbations we want to trace and for which instruments are available. We denote \( z_{it} \) as the IV introduced in the previous section and based on whether countries peg their currency to a base country and impose capital controls or not.

Next, consider two additional vectors of variables. The vector \( \Delta W_{it} \) includes all the variables in the system observed at time \( t \) for country \( i \) except for \( \Delta y_i t \) (given our timing convention, this is the first left-hand side variable) and \( \Delta y_i t \), which we explicitly instrument for. We will discuss the specific variables included in the analysis momentarily. In addition, the vector \( \Delta X_{it} - 1 \) contains the lags of all the elements in \( \Delta W_{it} \) as well as the lags of \( \Delta y_i t \) and \( \Delta y_i t \). The notation \( \Delta \) indicates that the variables in the system are all expressed as first differences.

Using these variable definitions, we are interested in estimating the dynamic multipliers of \( \Delta y_{it} - 1 \) for \( h = 0, 1, \ldots, H \) to an exogenous perturbation in \( \Delta r_{it} \). Identification of this exogenous perturbation is achieved in two ways. First, by using a rich set of controls to isolate the selection mechanism based on observables. This is done via the auxiliary vectors \( \Delta W_{it} \) and \( \Delta X_{it} - 1 \). Specifically, notice that the vector \( \Delta W_{it} \) has the same timing as \( \Delta r_{it} \). This is intentional, so as to manage the effect of home conditions observed within the year. The second basis for identification uses the IV \( z_{it} \) for \( \Delta r_{it} \) to account for selection based on unobservable factors. In practice, both sets of variables (controls and instrument) are used in the first stage regression, of course. Below we discuss the properties of the instrument in the context of this first stage regression.

Using these variable definitions, the specification of the local projections is

\[
\Delta y_{it-1} = \alpha_i + \beta_i \Delta r_{it} + \Delta W_{it} \gamma_i + \Delta X_{it-1} \delta_i + u_{it-1}.
\]  

(2)

which can be estimated by IV regression methods using \( z_{it} \) as the additional instrument for \( \Delta r_{it} \). The \( \alpha_i \) are country-fixed effects and in the estimations below we use country-based cluster-robust standard errors. The dynamic multipliers of interest are therefore the IV estimates of \( \beta_i \) for \( h = 0, 1, \ldots, H \). We generically designate
these as LP-IV coefficients, short for local projection instrumental variables. Estimates of the specification in expression (2) reported below therefore include a rich set of controls contemporaneously and in the lag structure. The objective is to stack the odds against our instrument as much as possible in the following sense. We want to isolate fluctuations in the short-term interest rate that are not explained by home economic conditions, but rather are correlated with short-term fluctuations in the base country (in situations where the home economy pegs its currency). Including a rich set of domestic controls soaks up variation in the base country’s short rate related to the home economy. This is the best insurance against finding that the estimated responses reflect endogenous fluctuations of the response variable given the data that we have. We will show momentarily that even with a saturated specification, the instrument remains highly relevant in most cases.

A truly exogenous instrument would allow us to estimate the responses without having to account for observable controls. In this case correlation between the base and the home economies makes including controls unavoidable. Unfortunately, we are unable to explicitly test for the exogeneity of the instrument using a test of over-identifying restrictions. Expression (2) is just-identified. Where appropriate, we report the results both with and without controls (the latter are provided as a robustness check). Data availability imposes considerable restrictions on the pre-WW2 sample. As a result, it is useful to show the results that omit controls but use a longer sample to check the estimates against those from the more limited sample. Moreover, we also provide (again, as a robustness check) a comparison of the results based on OLS estimates of expression (2) to characterize the bias in the OLS estimates.

7. Monetary conditions, credit growth, and house prices

Section 2 discussed secular trends in mortgage lending that suggest that bank lending experienced a considerable shift toward real estate financing after WW2. This section focuses instead on short-run fluctuations. Our instrument captures movements in short-term interest rates relative to movements that would have likely prevailed under a floating exchange regime and full control of domestic monetary policy.

Our analysis proceeds logically in sequential steps. First, we examine how persistently exogenous perturbations propagate to short-term interest rates. The rational expectation hypothesis of the term structure suggests that expectations on future short-term rates, adjusted for risk, drive longer term-rates. Therefore, next we trace how short-term rate fluctuations reverberate to long-term rates. Long-term rates tend to be very highly correlated with mortgage rates and therefore provide a good proxy measure for the price of mortgages (for which we do not have direct observations). Thus, we examine how the quantity of mortgages (normalized by GDP) responds to our pseudo-experiment. Ultimately, the availability of credit makes home buying more accessible. Higher demand for houses through cheaper financing tends to put upward pressure on home prices. The last link in the chain of events thus consists of characterizing the response of house prices to the shock in the short-term rate.

7.1. The instrument is relevant

As a first check, we evaluate the strength of the instrument introduced in Section 4 in the context of expression (2). We estimate the first stage regression of $\Delta y_t$ on $z_{it}$ and the other regressors in expression (2) including country-fixed effects. Then we report the F-statistic for the coefficient on $z_{it}$ constructed with country-based, cluster-robust standard errors. We note that since we only have one endogenous regressor, typical tests of instrument relevance, such as Kleibergen and Paap (2006) rank test, are roughly equivalent to the heteroskedasticity and autocorrelation robust Wald tests from OLS in the first stage. Due to gaps in data availability, we obtain different estimates of the Kleibergen and Paap (2006) statistic when we report our response estimates in Table 5 below (and later when we report robustness checks). We provide here simple first stage regression results to illustrate the instrument’s basic features.

The four response variables of interest include: (1) the short-term interest rate; (2) the long-term interest rate; (3) the ratio of mortgage loans to GDP; and (4) the log ratio of house prices to per capita income. When these variables are used as a left-hand side variable in expression (2), we take the h-difference $\Delta y_{ht} - 1$ described earlier. When the variables enter as controls, these variables enter as simple first differences. All of these variables are measured in percent change to facilitate the interpretation of the results.

Additional controls include: (i) the growth rate of real GDP per capita; (ii) the CPI inflation rate; (iii) the investment to GDP ratio; (iv) the ratio of non-mortgage lending to GDP; and (v) the ratio of the current account to GDP. We include up to two lags of each variable in the vector $\Delta y_{ht} - 1$. In what follows we report the $\beta_0$ coefficients in expression (2) but omit estimates of the fixed effects and the control set for brevity. We implement the analysis for the full sample and

Notes: $\Delta y_t$ denotes change from year $t - 1$ to $t + h$. $**$ p < 0.10, $***$ p < 0.05, $****$ p < 0.01. Country-based cluster-robust standard errors in parentheses. Coefficient estimates of fixed effects omitted. No other controls included in the regression. Kleibergen and Paap (2006) statistic for weak instruments reported. World wars omitted. See text.
later as a robustness check, we split the sample at World War 2. In Section 2 we argued that the major developments in mortgage lending took place starting in the second half of the 20th century. Table 4 reports first-stage regression results. The short rate is regressed on our instrument \( \Delta z \). We report two regressions. In the first block of results (columns 1–3) we omit the controls, in the second block (columns 4–6) we include them. The reason is that the sample sizes can vary quite a bit. Some of the controls are not available for some countries, especially in the first part of the sample. We consider three samples: all years, and the pre- and the post-WW2 years. In all cases we omit the world wars.

The results in Table 4 provide tangible intuition about the strength of the instrument. The instrument is relevant, although a bit weaker in the pre-WW2 era (columns 2 and 5). Even after adding a very rich set of controls and fixed effects (columns 4–6), the instrument remains significant across samples with high F-statistics (and hence significant coefficient estimates). The pass-through of fluctuations in the instrument onto the short-term rate ranges as high as 0.8 (column 1) to 0.3 (column 2), which is economically sensible. Thus, the intuition from the scatter plots in Section 4 is well supported by the more formal analysis reported in the table.

7.2. Estimates of the impulse responses

Table 5 reports estimates of the LP-IV coefficients in expression (2) for each of the response variables (1)–(4) described in the previous section. The perturbation is to the short rate via the instrument, the responses reported are of the short and long rates, mortgage loans as a ratio to GDP and house prices over per capital. The table is organized as follows. For each response we report coefficient estimates of the LP-IV coefficient using all years except the two world wars. Below we check for robustness to different subsamples. In addition, we report summary regression statistics along with the Kleibergen and Paap (2006) test of weak instruments.

In addition, Fig. 8 contains four panels that display each of the four impulse responses reported in the table. The experiment depicted in these panels is a negative one percentage point decline in the short rate due to exogenous fluctuations in the instrument. We use this normalization so as to more closely characterize the recent experience of several countries in the periphery of the Eurozone and described in Section 3. However, notice that the table reports the coefficient estimates directly from the regression output, which have the natural interpretation of a positive type of experiment instead. In other words, we flip the sign of the coefficient estimates from the table to construct the figure. We comment on the results for each variable, one at a time, starting with the response of the short rate to exogenous perturbations captured by the instrument. The results correspond to the first row block in Table 5 and panel (a) in Fig. 8.

These results include country-specific cluster-robust standard errors. Clustering by country allows for fully flexible time series dependence in the errors within country blocks. Typical heteroscedasticity- and-autocorrelation (HAC) robust estimation procedures impose non-parametric, monotonically declining temporal dependence. If these conditions are met and if assumptions about the rate at which this dependence rate decays are also correct, a HAC estimator provides a more efficient approach to correct inference. Relying on clustering alone is more general than using a HAC estimator. However, cluster-robust standard errors tend to be more conservative. Rather than a flaw, we view this as an advantage. By showing that our estimates are significantly different from zero using correct (but more conservative) standard errors, we provide the reader an extra degree of insurance against spurious findings.

Year 0 is the year when the shock is felt and the coefficient is therefore automatically normalized to one percentage point (for this reason we omit reporting standard errors and the \( R^2 \), which is equal to one). This will be the size of the perturbation with which to interpret subsequent responses. The effect of this perturbation is persistent and hump shaped. Years 1 thru 3 indicate that much of the effect on the short-term interest rate remains intact. Only in year 4 do we see the effect subsiding.

The persistence of the short rate response sets the stage for the analysis of the response of the long rate reported in the second row block of Table 5 and panel (b) in Fig. 8. The responses dampen relative to the short rate responses in a pattern entirely consistent with what is commonly found in the literature on term structure models (see,
Table 9
Classifying financial crises using mortgage lending and house prices. Logit models and AUC statistics for correct classification frontiers, full, pre-WW2, and post-WW2 samples.

| (a) Logit models, country fixed effects |
|------------------|------------------|------------------|
| Mortgage loans/GDP, lagged 5-year change | 0.14 0.00 0.25* | (0.10) (0.15) (0.13) |

| $H_0$: AUC model = AUC benchmark (p-value) | 0.01 0.10 0.05 |

Notes: * $p<0.10$, ** $p<0.05$, *** $p<0.01$. Dependent variable takes the value of 1 when there is a crisis for a given country-year, 0 otherwise. Panel (a) reports logit coefficients and standard errors in parentheses. Correct classification frontier for column (1) shown in Fig. 9. In panel (b) AUC benchmark refers to the AUC for a null logit model with country fixed effects only, but no other controls. AUC model refers to the AUC for the logit model whose coefficients we report. World wars omitted. See text.

Fig. 9. Classifying financial crises using mortgage lending and house prices.

An economic structure. Three responses should assuage such concerns. First, the sampling distribution of the impulse response estimates, itself a summary statistic of the heterogeneity in the data, indicates that our estimates have relatively contained dispersion. Second, using our historical dataset, Gadea-Rivas et al. (2014) show that there is more heterogeneity across time than there is across countries. Third, one of the robustness checks we provide is a detailed subsample analysis that shows that our findings are very stable to using data from different historical eras.

Another potential concern, despite the many precautions that we adopt in the analysis, is that our results are driven by reverse causality. That is, could it be that a surge in the demand for housing explains the behavior of house price mortgages and interest rates? We think that this mechanism can be easily ruled out. A surge in demand for housing would put simultaneous pressure on house prices and mortgages, which would translate into higher, not lower interest rates. For this reason, we feel reasonably confident that we have identified the correct channel linking a low interest rate environment with higher mortgage activity and house price appreciation. Our analysis provides a precise quantification of all these effects. In the next section we evaluate the robustness of these initial conclusions.

8. Robustness

This section examines the reliability of the conclusions reached in the previous section to a variety of modifications in the analysis. We begin by exploring the benefits of the IV approach. Would the responses look much different had we estimated expression (2) by OLS? The answer turns out to be yes and we provide a comparison across methods to assess the extent of the attenuation bias that IV estimation alleviates. Next, some of the variables in the dataset do not extend quite as far and wide. This limitation results in a smaller sample available for estimation. Consequently, we re-estimate Table 5 but omit the controls so as to evaluate whether a larger sample could significantly change the results. As we will show, the estimates remain fairly stable considering that we omit an important set of controls. Finally, we consider the robustness of the analysis to different subsamples. Would the results still hold up if we focus on the pre- versus the post-WW2 eras? What about omitting the Bretton Woods era of fixed exchange rates? These and other alternatives are investigated below.

8.1. OLS versus IV

How useful is our IV? Table 6 provides a direct comparison of the IV estimates reported in Table 5 with estimates obtained using OLS in expression (2). For brevity, we do not report estimates of the country-fixed effects or the control set. We omit the general regression statistics.
and focus exclusively on the coefficient estimates and their standard errors. The table is organized into four row blocks, one for each of the response variables we have considered so far.

The general patterns of the responses are similar across methods but the coefficient estimates from OLS are greatly attenuated with respect to their IV counterparts. The OLS response of the short and long rates is between a third and one half the response calculated using IV. Not surprisingly, the response of mortgage lending is more muted, although here the degree of attenuation is much more noticeable. Nevertheless, these three responses are estimated fairly accurately and the broad contours of the analysis from the previous section would survive largely intact.

On the other hand, the response of house prices varies more noticeably. First, based on OLS the coefficient of the response during years 0 and 1 is positive. This means that in response to a decline in the short rate (and a companion decline in the long rate and an increase in mortgage lending) house prices actually increase (albeit not significantly from the statistical point of view). Here the OLS bias not only attenuates the coefficient but it switches the sign and generates a response that is economically counterintuitive. The signs are correct for years 2 to 4 although again, the coefficient estimates are considerably attenuated relative to their IV counterparts. Compare the −0.90% year 4 response using OLS versus the −4.37% response obtained with IV. We conclude from this analysis that our instrument is capturing movements in the short rate that are more likely to reflect exogenous fluctuations than fluctuations we could identify using a simple OLS regression control strategy.

8.2. Responses when controls are excluded

The identification strategy rests on two pillars: the IV and a rich set of controls to purge possible common base and home economic factors driving fluctuations in the instrument. In a classical IV setting, a truly exogenous instrument would be sufficient to address bias induced by omitted controls. As a robustness check, we therefore reestimate the responses reported in Table 5 but omitting all controls except the country fixed effects. Omitting the controls results in a considerably larger sample, which also serves as an additional robustness check.

Table 7 replicates Table 5 but excludes the controls ΔWt and Δxt − 1 from expression (2). The table is organized into four row blocks, just as Table 5. The results reported in Table 7 are broadly comparable to those in Table 5. The response of interest rates, both short- and long-term are in fact virtually indistinguishable. The response of mortgage lending is similar but more attenuated. Four years out the cumulative effect is −1.41 when controls are omitted versus −2.82 when controls are included. Similarly, the response of house prices at year 4 is −2.96 when controls are excluded, versus −4.37 when controls are included.

Another way to interpret these results is in the context of the OLS versus IV comparison of Table 6. The attenuation bias we described in the previous section is largely resolved by using IV estimation.

8.3. Robustness to sample choices

The final set of robustness checks explores different ways to partition the sample and to construct the instrument. We consider five alternative scenarios. The analysis in Section 2 suggests that the share of total lending dedicated to mortgage lending began its ascent at the end of World War 2. A natural exercise is to examine the sensitivity of our results to partitioning the sample before and after World War 2. Call them scenarios (1) and (2). Next, we assess the sensitivity of the results to our construction of the instrument. We do this in two ways: by treating the Bretton Woods era as non-instrumented; and more drastically, by excluding this period entirely from the sample. Call these scenarios (3) and (4). Finally, the interwar period is particularly volatile (it includes the Great Depression). As a final check, we re-estimate the responses using a sample that excludes the period 1914 to 1972, that is, also excluding the Bretton Woods era. Call this scenario (5). In order to economize space, we report only the coefficients of each response in year 4 along with summary regression statistics.

Table 8 replicates baseline results from the full sample in year 4 from Table 5. These results are reported in column (0), which serves as a benchmark for each of the five scenarios just described and reported in columns (1)–(5). Several results deserve comment. Except for the pre-WW2 results reported in column (1), the stability of our findings across experiments is quite notable. The responses of the short and long rates vary over a very narrow range of about 0.1 to 0.15 percentage points. The variation in the responses to mortgage lending and house prices is a little wider, but so are the responses themselves. In the case of mortgage lending, the response varies from −2.67 to −3.47 and in the case of house prices it can vary from −4.37 to −5.88. These ranges of variation are in any case quite a bit smaller than the 95% confidence intervals implied by estimates themselves. Post-WW2 responses are more volatile, in part because the sample has more gaps, in part because it contains the more volatile interwar period (which includes the Great Depression), and in part because the role of mortgage lending (and the behavior of credit more generally) changed around the end of World War 2. Nevertheless, even the results in column (1) do not stray far from the results in column (0) or those in columns (2)–(5), which is reassuring.

9. Mortgage lending, house prices and financial crises

Section 6 showed that loose monetary conditions make credit cheaper, purchasing a home easier, and therefore houses more expensive. One of the narratives of the recent global financial crisis puts at its center a similar mechanism, see e.g. Mian and Sufi (2010, 2014).

Yet alternative narratives for the global financial crisis have emerged too. Some emphasize the role of excessive sovereign debt (e.g., Reinhart and Rogoff, 2009), and others the interplay between private and public debt (e.g., Jordà et al., 2013). Fears that the sovereigns will be unable to absorb losses in the banking sector can put into question the solvency of the sovereign itself. This fear quickly spreads to banks with substantial holdings of public debt, setting in motion what some call a “diabolical loop” (e.g., Brunnermeier et al., 2011). Jordà et al. (2013) found that crises are driven primarily by private credit rather than public debt, although their aftermath is certainly influenced by the level of public debt existing at their inception.

When it comes to financial crises, a growing consensus emphasizes the role of excessive private debt (see, e.g., Borio and White (2004); Schularick and Taylor (2012); Gourinchas and Obstfeld (2012); Jordà et al. (2013)). Moreover, some recent research has focused attention on the role played by households’ mortgage debt (Buyükkarabacak and Valev, 2010; Mian and Sufi, 2010, 2014), and in this paper we expand on these ideas by looking at the interaction between booms in housing debt that coincide with house price bubbles using the new long-run data introduced earlier.

This section explores these questions in historical perspective. Because financial crises are rare, we reach back in history and across a wide cross section of developed economies to examine the role that mortgage lending and house prices have exerted on the likelihood of experiencing a financial crisis. The chronology of financial crises relies on the dates available in Jordà et al. (2013) and the sources cited therein.

The dependent variable is binary and takes the value of 1 if for a given country-year pair there is a financial crisis, and it is zero otherwise. The two explanatory variables that we consider, mortgage lending as a ratio to GDP and house prices as a ratio to per capita income, enter as 5-year moving averages to parsimoniously capture conditions in the lead up to the crisis. In addition we include country fixed effects. On average, some countries have been more prone to financial crises than others and the fixed effects account for these differences. Our goal is not to thoroughly examine every possible factor and specification that
may determine when a financial crisis will happen. Rather we simply want to document the link between housing finance and financial crises.

Methodologically, we rely on classification methods rather than evaluating model fit. We are interested in evaluating the ability to sort into crisis versus no crisis events rather than in evaluating whether the conditional probability of a crisis is appropriately characterized by the model. The emphasis is on the informational content of the controls, not on the correct specification of the model. In other words, we are interested in knowing whether tomorrow will rain or not (a crisis will happen or not) in order to decide whether to carry an umbrella or not (take policy action that is costly but may prevent the crisis). We rely on a well-established literature in biostatistics and machine learning to provide suitable answers.

We approach the problem in two simple steps. First we fit a logit model of the crisis dependent variable using the mortgage and house price moving average controls as well as fixed effects. The model specification only acts as a tool to find suitable linear combinations of the controls whose informational content we then evaluate. Using predictions from this model, we then calculate true positive and true negative rates as follows. Consider the rule that calls a crisis whenever the predicted conditional probability from the logit exceeds a threshold $c \in [0, 1]$. This threshold need not be 0.5, in fact, it is allowed to vary. The true positive rate is the proportion of correctly called crises associated with any $c$ and the true negative rate is the proportion of correctly called non-crises instead. Choose a $c$ close to 1 and the true negative rate approaches 1 but the true positive rate deteriorates. The opposite happens when $c$ tends to zero. Given a classification technology, one can allocate information to predict one outcome or the other in different proportions depending on where the emphasis is needed.

The map of the true positive and true negative rates for each $c \in [0, 1]$ is a curve that Jordà and Taylor (2011) denote the correct classification frontier (CCF) in reference to the classic economic concept of a production possibility frontier. The better the classification technology, the further is this curve from the origin. A perfect classifier is one whose CCF is the unit square. By contrast, a classifier on the unit square is no better than random chance has a CCF equivalent to the diagonal bisecting the unit square. The area under the CCF is a measure of the model’s classification ability and is equivalent to the area under the receiver operating characteristic (ROC) curve or AUC, used frequently in biostatistics to evaluate medical tests (see, e.g. Pepe (2003) for a survey). The AUC for an uninformative classifier is readily seen to be equal to 0.5 (half the area of the unit square) whereas for the perfect classifier on the unit square it is 1. The AUC turns out to have an asymptotic Gaussian distribution, which makes this statistic convenient for hypothesis testing.

Table 9 summarizes the main results of this exercise for the full sample, and for robustness, the pre- and post-WW2 samples. The table is organized as follows. The top row-block shows the coefficient estimates whereas the bottom row-block provides each model’s AUC and a test of the null hypothesis that the AUC from the model is statistically equivalent to a benchmark AUC. The benchmark AUC is constructed using a model with fixed effects but no covariates. In addition Fig. 9 displays the CCF curve associated with the full sample results to provide a visual comparison of the CCF for the models with and without covariates.

The broad picture painted by these results is that mortgage lending and house prices have information about the likelihood of a financial crisis but that this information is clearly insufficient to generate a perfect prediction of financial crises. The numerical values of the coefficient estimates reported in the top row block of Table 9 are themselves of little interest. They are reported to illustrate the relative significance of the controls in the full sample specification. Loadings for the pre-WW2 sample are similar as those in the full sample although in the post-WW2 the loadings appear to be both on mortgage lending and house prices.

Nevertheless, there is non-negligible information in these covariates. The null benchmark AUC, from a model with fixed effects but no other covariates, is only 0.56. This is not significantly different from the reference AUC of 0.5 for a completely uninformative classifier. The interpretation is that, although there are differences in the rate of crises experienced across countries, these differences are small. AUCs from the benchmark model range from a low of 0.67 in the full and pre-WW2 samples, to a high of 0.71 for the post-WW2 sample, which is statistically different from the benchmark. As a complement, Fig. 9 displays the correct classification frontier for the full sample estimates, which forms the basis for the AUC calculations reported in the table.

What is the takeaway? Our historical analysis at business-cycle frequency outlines how accommodative monetary conditions can be accompanied by more mortgage lending and higher house prices. Both of these variables have been touted as possible factors in a financial crisis and our historical analysis using crisis prediction models suggests that there is some truth to this view. Moreover, we once more find evidence that these effects have become stronger with the rapid rise of real estate lending in the second half of the 20th century.

10. Conclusion

The global financial crisis brought to the fore trends in housing markets that had been brewing over the decades following WW2, a break from the relative stability of the pre-WW2 era. A mixture of financial liberalization, government support, risk taking by banks, and leveraging up by households brought about greater rates of home ownership across the developed world. Disentangling the importance of these various forces, which surely varied by time and place, is a difficult goal for future research, and is beyond the scope of this paper. Yet the rise of leveraged real estate booms has been identified by much recent research as being central to the understanding of financial crises. After presenting this historical evidence, this paper makes two key contributions to the understanding of the link between monetary conditions, mortgage credit and house prices.

We use fluctuations in monetary conditions that have their origin in macroeconomic conditions elsewhere as a natural experiment. Such fluctuations serve as IVs to trace dynamic responses of mortgage lending and house prices. At business cycle frequencies, we find robust evidence in support of a direct mechanism linking short-term rates, mortgage lending and house prices. Through the term structure, long-term rates respond to short-term rates, thus affecting the price of mortgages. In response to easing monetary conditions and hence a decline in the price of mortgages, mortgage lending expands. Rising house prices improve the value of the mortgage’s collateral, and with it a bank’s asset position and its ability to lend further. Loose monetary conditions are causal for mortgage and house price booms, and this effect has become much more dramatic since WW2.

It is natural to suspect that such a feedback loop could set in motion conditions for a housing boom and increased leverage, which in turn heightens the risk of a financial crash down the road. The long run view from economic history suggests that such mechanisms are a regular feature of the modern financial cycle, and we use statistical methods from the literature on binary classifiers to explore this question. Using logit models, the correct classification frontier, and tests based on the area under the curve, we find that over a 5-year window run ups in mortgage lending and run ups in house prices raise the likelihood of a subsequent financial crises. Mortgage and house price booms are predictive of future financial crises, and this effect has also become much more dramatic since WW2.

What are the implications of these findings for the ongoing debate about monetary policy in the post-crisis age? How much should central banks worry about the financial stability risks of loose monetary conditions? Our findings suggest the side-effects of easy low interest rates should be cause for some concern. Real estate lending has grown strongly during the 20th century and now accounts for the dominant share of bank lending in many countries; the sensitivity of mortgage lending and house prices to changes in monetary conditions has also increased substantially. A key implication of
this result is that central banks cannot pursue macroeconomic stabilization policy without being mindful of the consequences for credit markets and financial stability. However, none of this should be taken to imply that tighter monetary conditions are the right answer. The findings from our study call for a nuanced approach. Central banks should acknowledge that the trade-offs they face can potentially be managed through greater use of macro-prudential tools. Macroeconomic history refutes the notion that the joint objectives of macroeconomic stabilization and financial stability can be examined in isolation.
